Acknowledgment is due the following farm advisers for their collaboration in these tests:
H. C. GILKERSON, Lake county; D. E. WARREN, Ogle county;
H. K. DANFORTH, Henry county; G. T. SWAIM, Kankakee county;
R. T. NICHOLAS, Schuyler county; H. D. TRIPLETT, Ford county;
P. M. KROWS, Moultrie county; J. B. TURNER, Fayette county;
W. D. MURPHY, Edwards county; and E. C. SECOR, Randolph county.

Sixth Annual

Illinois Corn Performance Tests 1939

By R. R. COPPER, G. H. DUNGAN, A. L. LANG, J. H. BIGGER,
BENJAMIN KOEHLER, and OREN BOLIN¹

MORE THAN five and a half million acres of Illinois corn land were planted with hybrid seed in 1939, or 69 percent of the total corn acreage of the state. In central and northern Illinois the percentage of hybrid corn was even higher.

A favorable season, combined with the extensive use of hybrid seed corn adapted to the locality and to the soil where planted, resulted in an average yield over the entire state of 52 bushels an acre, the highest ever reached in Illinois.

SCOPE OF THE TESTS

A total of 331 hybrids and 29 open-pollinated varieties were included on the ten Illinois corn-performance test fields in 1939. This was the largest number of entries on record. On the central and north-central fields the number of entries was increased from 60 to 73 or 75, owing to demand on the part of producers for the opportunity to enter their crosses. The other fields included 61 entries or less. Five open-pollinated varieties were used as a check on each field. Forty-eight companies and individuals entered hybrid seed and 27 companies and individuals furnished the open-pollinated varieties.

Seed samples were taken from the warehouses of the producers entering the corn. Samples which were taken from less than five different bushel lots are marked with a star (*) in the tables. Whenever possible, the grade sampled was that known as "regular flat."

Not only were records made of the yields of the various entries, but measurements were also made of lodging resistance and soil adaptability.

SOIL CHARACTERISTICS OF FIELDS

The fields chosen for the 1939 tests were, on the whole, medium to high in productivity. In locating a field, effort was made to select a soil type that occurs extensively in the region represented by the field. Furthermore care was taken to have each field as nearly uniform

¹R. R. COPPER, Assistant in Crop Production, G. H. DUNGAN, Chief in Crop Production, A. L. LANG, Assistant Chief in Soil Experiment Fields, BENJAMIN KOEHLER, Chief in Crop Pathology, and OREN BOLIN, Associate in Plant Genetics, Illinois Agricultural Experiment Station; J. H. BIGGER, Associate Entomologist, Illinois State Natural History Survey.

as possible, both in soil type and in drainage conditions. At Shobonier small "slick spots" occurred thruout the testing field.

The general location of the ten test fields is shown by the map on page 216. General information on soil characteristics and soil-management practices is indicated in Table 2.¹

Drainage is described as *rapid*, *moderate*, and *slow*. When applied to the surface, *rapid drainage* indicates a tendency to erode, *moderate* indicates satisfactory runoff with minimum erosion, while *slow* indicates practically no natural surface movement. When applied to underdrainage, *rapid* indicates the existence of a drouthy condition, *moderate* indicates relatively free movement of excess ground water to tile but retention of sufficient moisture for normal plant growth, and *slow* indicates a nearly impervious subsoil.

METHOD OF PLANTING

Each test field was planted as described in Bulletin 427 (1936). On all but the Modoc field, each entry (variety or hybrid) was planted in 10 plots, each plot being 12 hills long and 2 rows wide. At Modoc 45 of the 57 entries were planted in 9 plots instead of 10.

All plots were planted 3 kernels to a hill, and the only correction made for imperfect stand was to adjust the yields for missing hills. All seed was treated with organic mercury dust before planting.

Entries were arranged in the controlled random order, as described in Bulletin 427. With the few exceptions indicated in the tables of results, all plots of each entry were harvested.

¹HERMAN WASCHER, Assistant Chief in the Soil Survey, determined the soil type, uniformity, and physical characteristics of each field. H. J. SNIDER, Assistant Chief in Soil Experiment Fields, made the chemical analyses.

SEASONAL CONDITIONS

At Kings, Cambridge, and Littleton—the north, west north-central, and west-central fields—growing conditions in 1939 were more favorable than at the other fields.

Temperatures during the growing season were satisfactory for all of the test fields, but rainfall distribution was not favorable on some of them. All the fields were planted in good moisture except the Albion field, which was rather dry. However, after the first cultivation at Albion there was an overabundance of rain, which slowed up the growth of the plants. All but the Shobonier field had ample moisture after planting, and the corn made an excellent start. The Shobonier field was dry until about the second week in June, but had plenty of rain for the main part of the growing season.

The abundance of rain early in the season on a few fields made for a slightly shallow root system, the effects of which appeared later during the long dry spell in August. The Paxton and Reddick fields in particular appeared to suffer on this account, and corn matured a little earlier than usual on these fields. The Libertyville field suffered the most from the late summer drouth and hot weather, the corn on this field showing some tendency to be light and chaffy. The corn on the Littleton and Cambridge fields remained green longer than on the other fields in the test, maturing at a more nearly normal time than on the other fields.

The abundance of moisture during July favored the development of ear rots and damaged corn, but the hot dry weather in August checked this condition. The Paxton and Albion fields had a greater amount of *Diplodia* ear rot than any of the others.

None of the test fields suffered any damage from hail or windstorms.

INSECT PROBLEMS

The Illinois corn crop suffered the minimum of damage from insects during the 1939 growing season. Just as this season was the most favorable one for corn on record, it was the least favorable one for insect development. Furthermore when plants are grown under conditions conducive to their maximum development, they can better withstand the attack of such insects as may be present.

At none of the test fields were there enough chinch bugs to produce measurable differences in the condition of the crop, nor was there any grasshopper problem in 1939. There are no records, therefore, of the relative ability of the different entries to withstand attack by these two insects.

The southern corn rootworm, *Diabrotica duodecimpunctata* Fab., was abundant enough on only two fields (Cambridge and Littleton)

to produce measurable effects on the corn plants. Even on these two fields the damage was not great, the average amount of lodging (plants leaning 30 degrees or more) of the hybrids being 14.4 percent at Cambridge and 13.6 percent at Littleton. Rootworms attacked the plants only in the early part of the season; and much of the corn that lodged because of this damage later elbowed and straightened up, so that the lodging was not noticeable on casual observation. It was measured, however, at harvest time, and is recorded in Tables 6A and 8A on pages 193 and 199.

Another type of insect damage appeared during the 1939 season. The corn leaf aphid, *Aphis maidis* Fitch, attacked the field near Libertyville at tasseling time. Damage was not extensive, a survey showing that only 1.2 percent of the plants were severely affected. However, a few entries were very susceptible to the aphid. The open-pollinated varieties were more susceptible than the hybrids, indicating that plant breeders are successfully producing hybrids resistant to this aphid.

DISEASE PREVALENCE

Disease losses were low in 1939 compared with those of 1938. But in spite of general high yields, certain diseases took a toll. Unquestionably some entries ranked low mainly because of injury from stalk rot.

Diplodia Stalk Rot. Premature dying of plants was first noticed in some hybrids in mid-August. By mid-September some stalks had died prematurely on nearly all the test fields and in most of the corn-fields of the state. On one day the leaves of the plant would be alive and on the next day they would be dead, as tho they had been frosted. A few days later they would change to straw color and the main stalk would be blanched. Where such plants were scattered thruout the field among the green plants—some dying one day, others the next, etc.—the stalks of all prematurely dead plants were invariably rotted severely by *Diplodia* (page 178). Usually some of the green plants also showed *Diplodia* stalk rot infections but to a less extent.

A count of the prematurely dead plants at a selected time was used as a measure of the degree of susceptibility of a hybrid to damage by *Diplodia* stalk rot. All the hybrids on a given field were checked for prematurely dead plants on the same day, and without knowledge by the checker of the identity of the entries.

Three fields—Sullivan, Littleton, and Cambridge—were best suited for the comparison of stalk-rot susceptibility (Table 3). Test fields farther south had the least stalk rot. All test fields in central and northern Illinois had considerable stalk rot, but as a number of the fields began drying up early in September regardless of stalk rot, the basis for judging stalk-rot susceptibility was obliterated. This general drying of fields was attributed partly to the late-season drouth.

Reduction in Yield From Stalk Rot. The appearance of stalk rot and the dying of plants occurred in 1939 at about the same dates as in 1938, but the damage to yield was considerably less. One probable reason for this fact was the unusually fast growth of the corn plants and the development of the ears earlier than in a normal season; another reason was that Stewart's disease caused less damage than in 1938. None of the entries, however, in which a large number of stalks died prematurely ranked very high in yield or in general performance, suggesting that significant damage was caused by stalk rot.

While it is not true that hybrids that are resistant to stalk rot are always high yielding, nevertheless correlations between yield and resistance to stalk rot are fairly good. At Cambridge the correlation was .466, at Littleton .752, and at Sullivan .409.

Stalk Rot and Stalk Breaking. There is considerable interest in the question to what extent stalk breaking indicates stalk rot. Data taken this year showed a very close relationship in some crosses and very little relationship in others. In a field of single crosses at Urbana the correlation between stalk breaking and stalk rot was only .123, which is not significant. Two tests with more single crosses conducted by the Independent Hybrid Producers of Illinois, Inc., gave correlations of .307 and .423; these figures are statistically significant, but here also some striking exceptions occurred.

Stewart's Disease. Stewart's disease did not cause as much damage to field corn in 1939 as was expected, considering the heavy infection that occurred in 1938 and the moderate winter that followed. True to predictions, however, early sweet corn was more damaged

Stewart's disease on leaves of dent corn

Infection is carried to the leaves by flea beetles. From points of infection the disease spreads mainly along the veins, killing the leaf tissue and leaving irregular streaks.

Hill of corn killed by Diplodia stalk rot

Plant at left shows typical surface discoloration; center plant shows the *Diplodia pycnidia*, visible as small black dots; the plant at the right is cut open to show rot in the interior.

than it had been for several years. Leaf infections in dent corn (page 178) could be found in late summer in nearly every field as far north as Joliet and Mendota but severe damage like that in 1938 failed to materialize. The very severe infection at Sullivan caused a loss of 20 percent of the leaf surface by September 12.

Ear Rots. Frequent moderate rains during the first half of summer made conditions ideal not only for corn growth but also for *Diplodia* infection. When the ears were in the milk stage, an alarming number of plants died from *Diplodia* rot in some fields. Unusual losses in yield, resulting from ear rot, were expected but a change to dry weather after early August checked this tendency, making state losses somewhat below the average of the last fifteen years.

The amount of ear rot in the performance tests is indicated in the tables under the heading "Damaged corn in shelled sample." The rot damage in 1939 was caused principally by *Diplodia*. While the exact significance of each one of those percentage figures is admittedly uncertain, there is no question that some hybrids are distinctly more resistant to ear rots than others.

In seven of the test fields the hybrid corn had less rot than the open-pollinated corn. The average damage from ear rot on all the fields was 1.67 percent for the hybrids and 1.76 percent for the open-pollinated varieties. These figures do not show a significant advantage for hybrids. The low losses in Illinois from ear rots during the last few years must be attributed in large part to seasonal conditions and other environmental factors rather than entirely to the planting of a greater acreage to hybrids. It is feared that this low point in the cycle of rots has led some to forget the seriousness of the ear-rot threat; and consequently that there will be much disappointment and complaint when, by the return of weather conditions favorable to ear rot, farmers are again faced with this problem.

Other Diseases. Moderate but adequate moisture and spring temperatures above normal resulted in good corn stands and little damage from seedling diseases. "Purple corn," a discoloration and stunting of young corn plants associated with phosphorus deficiency, was reported by farmers at numerous places in the state but did not appear on the test plots. Smut was of minor importance except in those inbreds and crosses especially susceptible to it.

DROPPED EARS

While a count was made of the dropped ears on all the test fields, there were too few such ears for any significant conclusions to be reached. They were reported very extensively in August in farmers' fields where *Diplodia* had done considerable damage and where high winds had occurred.

MEASURING PERFORMANCE OF ENTRIES

The entries in 1939 were rated, as they were each year since 1935, on the basis of two measures of performance—erect plants at harvest (lodging resistance) and yield of sound corn.

Erect Plants. The percentage of erect plants in each entry on each field was estimated at the time of harvest. The *rating* for erect plants of an entry is the ratio of erect plants of that entry to the average number of erect plants on the field, multiplied by 100.

There were three types of lodging on the test fields—that due to rootworm damage, to broken stalks just below the ear, and to broken stalks toward the base of the plant. Photographs on page 183 show the two latter types of lodging.

Sound Corn. To determine shelling percentage, the entire yield from one replicate of each entry was shelled. From this shelled corn one sample was taken to determine the percentage of moisture at harvest, and another to determine the percentage of damaged kernels, by weight. The moisture determinations were made with a Tag-Heppenstall moisture meter. The percentage of damaged corn was determined according to the Federal Grain Standards.

The total acre-yield was calculated as shelled corn carrying 15.5 percent moisture, the upper limit allowable for No. 2 corn. The yield of sound corn was computed by deducting the amount of damaged corn from the total yield.

The rating on sound yield is the ratio, expressed as percentage, of the yield of sound corn for that entry to the average yield of sound corn for all the entries on the field.

General Performance. In computing the general-performance rating of an entry, the ratings for erect plants and sound corn were averaged, but the sound-corn rating was given three times the weight of the rating for erect plants. When two or more entries tied in the general-performance rating, the ties were given the same numerical ranking, but they were listed in the order of their descending yield of sound corn. If the two entries had the same yield of sound corn, then they were listed on the basis of total corn.

Chance Differences. Too much confidence must not be placed in the exact ranking of a hybrid in the following tables, for chance has played a part in determining the placing of many of them. Unmeasured differences in soil and in prevalence of insects and diseases, and unaccountable variability in stand will cause differences in yield that are not inherent in the hybrids or varieties.

The part played by chance in the 1939 tests has been calculated by the mathematical procedure known as "analysis of variance." At the bottom or side of each table is stated the approximate difference

which there must be in the 1939 yields to show a true inherent difference between any two entries. Unless this difference exists there is no assurance that one entry is inherently higher yielding than the other.

Readers are urged to note the difference necessary for significance, as shown for each test field, and to keep that difference constantly in mind in all comparisons of entries on that field.

RESULTS OF 1939 PERFORMANCE TESTS

Northeastern. At Libertyville 51 of the 54 hybrids exceeded the general-performance rating of the best open-pollinated variety. The five best hybrids produced an average of 15.9 more bushels of sound corn than the average of the five open-pollinated varieties, while the five poorest hybrids averaged only 1.2 more bushels of sound corn an acre. In lodging resistance the five best hybrids were much better than the open-pollinated varieties, averaging 13.4 more erect plants per hundred; and the five poorest hybrids were better by 10 plants per hundred. The field was harvested October 12, a very early date for the region, but owing to the dry weather during the latter part of the season the corn averaged only 16.9 percent moisture content, with a range from 20.1 percent to 12.9 percent.

Northern. On the Kings field the five best hybrids exceeded the five open-pollinated varieties by an average of 23.8 bushels of sound corn an acre and 20.8 erect plants per hundred. The five poorest hybrids outyielded the five open-pollinated varieties by an average of 5.3 bushels of sound corn an acre and were much more resistant to lodging, having 18.4 more erect plants per hundred. These differences in favor of the five poorest hybrids were larger than those on any of the other test fields, and would seem to indicate that the hybrids were, as a whole, better adapted to this field than they were to the other fields. Fifty-four of the 55 hybrids on this field had a higher general-performance rating than any open-pollinated variety.

West North-Central. The average production of all entries on the Cambridge field was 114.4 bushels of sound corn an acre, the best yield for any field in the six years of the Illinois corn-performance tests. This field is also credited with the highest yielding individual entry, the best hybrid producing 129.3 bushels of sound corn an acre. With these high yields the five best hybrids surpassed the five open-pollinated varieties by an average of 27.6 bushels of sound corn an acre and they had 17.6 more erect plants per hundred. The five poorest hybrids exceeded the open-pollinated varieties by an average of 2.4 bushels of sound corn an acre and 9.8 erect plants per hundred. Sixty-nine of the 70 hybrids in the test exceeded the average general performance of the open-pollinated varieties.

East North-Central. On the Reddick field 65 of the 68 hybrids in the test had higher general-performance ratings than the average of the open-pollinated varieties, and 61 hybrids had higher ratings than any individual open-pollinated variety. The five best hybrids outyielded the open-pollinated varieties by an average of 16.0 bushels of sound corn an acre and had 11.6 more erect plants per hundred. The five poorest hybrids averaged 2 bushels less of sound corn an acre than the open-pollinated varieties and had 1.4 fewer erect plants per hundred. Corn on this field matured very early and had very little moisture when harvested.

West Central. On the Littleton field the five best hybrids averaged 15.6 bushels more of sound corn an acre than the open-pollinated varieties, and the five poorest hybrids averaged 5.5 bushels less than the open-pollinated varieties. Both the five best hybrids and the five poorest hybrids surpassed the open-pollinated varieties in lodging resistance, the hybrids having 17.6 and 10.8 more erect plants per hundred respectively. Sixty-four of the hybrids had a higher general-performance rating than the average of the open-pollinated varieties.

East Central. The Paxton field had 68 hybrids with higher general-performance ratings than the average of the open-pollinated varieties. The five best hybrids outyielded the open-pollinated varieties by an average of 15.6 bushels of sound corn an acre, and were much more resistant to lodging, having 14.6 more erect plants per hundred. The open-pollinated varieties, however, outyielded the five poorest hybrids by an average of 3.7 bushels of sound corn an acre, tho they were not nearly so resistant to lodging, having 15 fewer erect plants per hundred. Some of the entries on this field were badly damaged by *Diplodia* ear rot.

South Central. Along with the higher yield that was produced on the Sullivan field in 1939 compared with 1938, more hybrids had higher general-performance ratings than the average of the open-pollinated varieties—51 hybrids in 1939 against only 26 in 1938. The five best hybrids averaged 14.2 more bushels of sound corn an acre than the average of the open-pollinated varieties, while the five poorest hybrids averaged 5.8 bushels less. In lodging resistance the five best hybrids were superior to the open-pollinated varieties, averaging 12.9 more erect plants per hundred; the five poorest hybrids had a better average by 9 plants.

Southern. In the 1938 tests at Shobonier the open-pollinated varieties clearly surpassed the hybrids, but in 1939 this situation was completely reversed, the five best hybrids averaging better than the six open-pollinated varieties by 12.2 bushels of sound corn an acre, and the five poorest hybrids averaging better by 1.3 bushels. Also in resistance to lodging, both the five best and the five poorest hybrids averaged

Two types of lodging on the test fields

Left, lodging caused by *Diplodia* stalk rot near the base of the plant. *Right*, lodging caused by stalk breaking below the ear of the plant.

better than the open-pollinated varieties, each group of hybrids having 5.7 more erect plants per hundred. The greater superiority of the hybrids over the open-pollinated varieties in 1939 was due in part to the more favorable growing conditions of 1939. Both hybrids and open-pollinated varieties had higher percentages of erect plants in 1939 than in 1938.

Southeastern. On the Albion field 46 of the 48 hybrids in the test had a higher general-performance rating than the average of the open-pollinated varieties. The five best hybrids outyielded the open-pollinated varieties by an average of 13.1 bushels of sound corn an acre, while the five poorest hybrids produced 1.6 bushels less than the open-pollinated varieties. In lodging resistance the five best hybrids and the five poorest hybrids were superior to the open-pollinated corn, averaging respectively 6.0 and 5.8 more erect plants per hundred. Considerable rootworm damage occurred on this field; and had there been rain with strong wind during the last part of the season there would have been considerable lodging of plants.

Southwestern. At Modoc the five best hybrids outyielded the open-pollinated varieties by an average of 20.6 bushels of sound corn an acre and the five poorest hybrids outyielded the open-pollinated varieties by 2.8 bushels. In lodging resistance the five best hybrids were superior to the open-pollinated varieties, averaging 7.2 more erect plants per hundred; the five poorest hybrids were superior by 4 plants per hundred. In general-performance rating 51 of the 52 hybrids in the test exceeded the average of the open-pollinated varieties.

FOUR-, THREE-, AND TWO-YEAR SUMMARIES

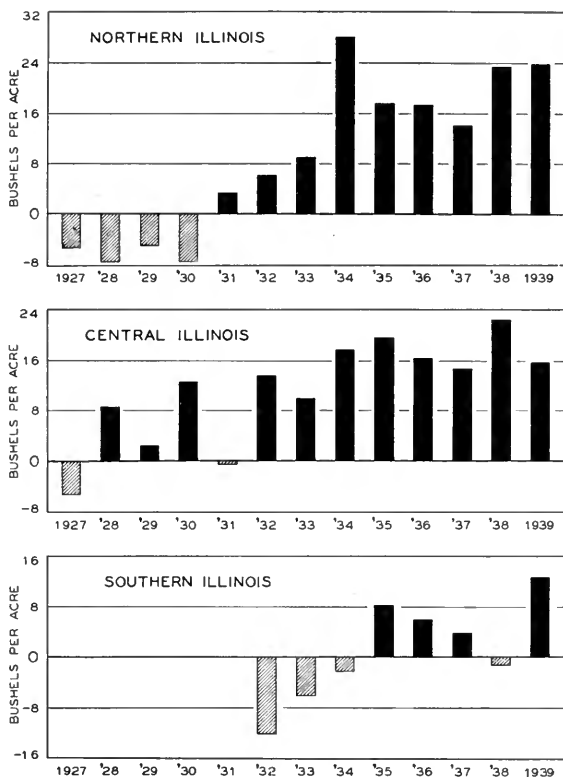

One obstacle in the corn-improvement program is the tendency for commercial producers of hybrid seed corn to base their evaluations of some inbred combinations on too limited tests. More thoro testing thru several seasons will later disclose weaknesses that were not apparent in the more limited tests. Obviously then the more seasons thru which a corn has been tested, the more certain a grower can be of its value. The tables giving the yield and performance of entries that have been included in these tests for two or more years are therefore of special interest. Such a table for each field except Modoc follows immediately after the table giving the 1939 results for the field.

Because of the rapid introduction of new hybrids and the dropping of less desirable ones, there are relatively few entries in the four-year summaries and this of course lessens their value. To get the most out of these data the four- and three-year averages will have to be studied along with the two-year and current year's results.

For seven of the ten fields operated in 1939 four-year summaries are presented. For nine fields both three-year and two-year averages are available. Data obtained in 1939 from the Modoc field in extreme southwestern Illinois are not averaged with those obtained at Golconda and Elizabethtown in 1937 and 1938 because of the widely different soil and climatic conditions represented by these two fields—Modoc being in the Mississippi valley and the other two in the Ohio valley.

One of the goals toward which plant breeders have been working
This particular plot on the Paxton field stood 100 percent.

Differences between yields of hybrids and open-pollinated varieties 1927-1939

The above bars show the amounts by which the yields of the five best hybrids have exceeded (*black*) or have fallen below (*crosshatch*) the five best open-pollinated varieties, in three sections of Illinois.

A further summarizing of the four-year, three-year, and two-year data for nine fields is shown in Table 17 (page 215). On most fields the four-year average yield of sound corn by the hybrid entries exceeded that of the open-pollinated varieties by a greater margin than did the hybrids that have been tested for the past two or three years only. On the northern and west north-central fields the average superiority of the hybrid yields over the open-pollinated yields in the four-year period was a little less than the corresponding figure for the three-year and two-year averages. The differences, however, were only slight. Thus even tho a few hybrids in the shorter-term averages may be superior to those in the four-year tests, it is evident that those in the four-year tests are not only high yielding but consistent in performance.

*Less than 5 bushels of seed sampled. ¹Average of 9 plots instead of 10. ²Average of 8 plots instead of 10. ³Average of 7 plots instead of 10.

A difference of less than 6.4 bushels between total yields of any two entries in this table is not significant.

SOIL ADAPTATION TESTS

Studies of the relation of soil productivity to hybrid corn performance were continued in 1939 at Sibley and Urbana. Ideal areas for this purpose were available at each location.

Soils. The fertile area at Sibley consists of Proctor silt loam on which alfalfa has been grown for the past two years. The less fertile area is an untreated heavily cropped Elliott silt loam which is badly eroded on the more sloping parts. At Urbana the two areas, which are on the Agronomy south farm, differ in productivity as a result of the long-continued use of different cropping systems. In the Southwest rotation a high state of productivity has been maintained by systematically rotating corn, oats, hay, and wheat with a red-clover catch crop. The South-Central area has been depleted of fertility by a rotation of corn, corn, corn, and soybeans. Both plots at Urbana have received manure and phosphate. The Southwest rotation has had slightly more limestone than the South-Central. The soil type of the two fields is mainly Muscatine silt loam.

Season. The weather in 1939, which favored high yields, was fairly uniform at all locations. Mechanical difficulties in planting and cultivating caused a very irregular stand on the better soil at Sibley, reducing yields and the reliability of the ratings. The less productive area at Urbana suffered during and after midseason from a lack of available nitrogen. This condition caused weakness of stalk, which resulted in severe lodging accompanied by light chaffy corn with many defective kernels.

Results. The 1939 results were not greatly different from those in 1937 and 1938, equally high yields being produced in all three years. Hybrids demonstrated their capacity for high yields especially on the highly fertile field at Urbana. The average yield of the five best hybrids on the soil of high fertility was 19.7 bushels better than Station Yellow Dent. At Sibley on soil of low fertility the yield of the five best hybrids was 15.3 bushels above the yield of the open-pollinated varieties. This exceptionally wide difference at Sibley on the low-fertility level was probably due in part to favorable weather causing an especially high yield and in part to the wider adaptability that is being developed in hybrids. Adapted hybrids have much greater resistance to unfavorable conditions than most of the open-pollinated varieties.

The 1939 tests emphasize again the great importance of maintaining the soil in a high state of fertility if advantage is to be taken of the high-yielding capacity of the better hybrids. On the highly fertile soil at Urbana, U. S. Hybrid 5 demonstrated, by standing at the top of the list, that it has a great capacity for utilizing plant food. This hybrid has ranked at the top or near the top for four consecutive years. On the less fertile soil, however, it has never had a high ranking.

¹Owing to unfavorable conditions, the stand on this plot was very irregular and ratings therefore are not significant.

Averages. A summary of the performance of the three hybrids that have been included in the plantings on all four areas during the past four years is given in Table 16 (page 214). Some rather important contrasts are shown in this table. On the highly fertile soils U. S. Hybrid 5 stands out, with the highest average yield of 92 bushels an acre, which is 16 bushels better than the yield of the open-pollinated variety, Station Yellow Dent. On the soil of low productivity U. S. Hybrid 5 yielded only 49 bushels an acre, only 8 bushels better than the open-pollinated variety. These tests thus demonstrate the capacity of U. S. 5 to utilize the plant-food materials in highly fertile soils more

satisfactorily than hybrids Illinois 960 and Sibley Estate 588 and to utilize it less satisfactorily than these two hybrids on soils of relatively low fertility.

From these data it might seem that yield alone would always be a safe basis for selecting a hybrid for a particular type of soil, but there are other physical characteristics that must also be considered. Capacity to maintain lodging-resistance, disease-resistance, and normal ear and kernel development when grown on poor soil is very important.

Some differences in the ear characteristics of different hybrids grown on soils of high and low fertility are illustrated on pages 212 and 213.

¹U. S. Hybrid 5 was tested as Illinois 139 in 1936 and in 1937, as a coded commercial hybrid.

SUMMARY

1. The average yield of corn on the ten fields in the Illinois corn-performance tests in 1939 was 80.2 bushels an acre, which is 28.2 bushels more than the average for the state. During the six years (1934-1939) over which these tests have been conducted, the average yields on the test fields have exceeded the average yields of the state by 111, 94, 79, 64, 47, and 53 percent respectively.

2. The five best hybrids on all the ten fields in the 1939 Illinois corn-performance tests yielded an average of 16.5 bushels of sound corn an acre above the five open-pollinated varieties. They also exceeded the open-pollinated varieties in lodging resistance, having 12.7 more erect plants per hundred.

3. On every test field the five best hybrids exceeded the five open-pollinated varieties in yield of sound corn and in percentage of erect plants. On the southern Illinois field, where in 1938 the five best hybrids fell below the five open-pollinated varieties in sound corn yield, the superiority of the five best hybrids was 12.2 bushels an acre.

4. In the northeastern, northern, west north-central, southern, and southwestern sections of the state even the five poorest hybrids averaged above the open-pollinated varieties in yield of sound corn.

5. Four-, three-, and two-year summaries are presented for all the fields except the southern, southeastern, and southwestern. The average yield of the hybrids in relation to the open-pollinated checks in the four-year summary compares favorably with the average of the hybrids in the three-year and two-year summaries.

6. Insect damage was not very extensive in 1939. Southern corn rootworm did some noticeable damage on the Littleton and Cambridge fields. Corn leaf aphids attacked the Libertyville field at tasseling time.

7. Comparisons for susceptibility to stalk rot were made on the Sullivan, Littleton, and Cambridge fields. Hybrids that were markedly

susceptible to *Diplodia* stalk rot were low yielding. Stewart's disease was most severe on the Sullivan field. There was some damaged corn on all test fields due to ear rots, but the hybrids appeared to have no striking advantage over the open-pollinated varieties with respect to resistance to these rots.

8. The soil-adaptation tests showed that hybrid corn grown on soil of high fertility will produce very high yields. In fact, the yields of hybrids are much more markedly increased by good soil-treatment practices than are the yields of open-pollinated varieties. Hybrids, however, do not perform even relatively as well on poor soils as they do on good soils. Certain physical characteristics—such as the tendency of the plant to lodge, susceptibility to disease, abnormal ear and kernel development—are sometimes as important in determining the adaptability of a hybrid to a given soil as are the yields of grain produced.

LOCATION OF 1939 TEST FIELDS

Ten fields, distributed so as to represent the more important climatic areas of the state, were used in the 1939 general-performance tests; two others, Sibley and Urbana, were used in soil-adaptability tests.

The fields chosen for the tests were, on the whole, medium to high in productivity.
